Questions

1.

- What is the learning algorithm being used to optimize the weights of the neural networks?
- What are the parameters (arguments) being used by that algorithm?
- What loss function is being used?
- Please, give the equation(s)
- 2. For each experiment excepted the last one (shallow network learning from raw data, shallow network learning from features and CNN):
- Select a neural network topology and describe the inputs, indicate how many are they, and how many outputs?
- Compute the number of weights of each model (e.g., how many weights between the input and the hidden layer, how many weights between each pair of layers, biases, etc..) and explain how do you get to the total number of weights.
- Test at least three different meaningful cases (e.g., for the MLP exploiting raw data, test different models varying the number of hidden neurons, for the feature-based model, test pix_p_cell 4 and 7, and number of orientations or number of hidden neurons, for the CNN, try different number of neurons in the feed-forward part) describe the model and present the performance of the system (e.g., plot of the evolution of the error, final evaluation scores and confusion matrices). Comment the differences in results. Are there particular digits that are frequently confused?
- 3. The CNNs models are deeper (have more layers), do they have more weights than the shallow ones? explain with one example.
- 4. Train a CNN for the chest x-ray pneumonia recognition. In order to do so, complete the code to reproduce the architecture plotted in the notebook. Present the confusion matrix, accuracy and F1-score of the validation and test datasets and discuss your results.

Learning algorithm

We will use the same learning algorithm for all the experiments: RMSprop. We will also use the same parameters for all the experiments.

Optimizer:	RMSprop
learning_rate:	0.001
momentum:	0.1
loss:	categorical_crossentropy
batch_size:	128
n_epoch:	50

The equation for the loss function is:

$$E[g^{2}]_{t} = \beta E[g^{2}]_{t-1} + (1 - \beta)(\frac{\delta C}{\delta w})^{2}$$

$$w_{t} = w_{t-1} - \frac{\eta}{\sqrt{E[g^{2}]_{t}}} \frac{\delta C}{\delta w}$$

How the number of weights is calculated

The number of weights between two layers is calculated by multiplying the number of neurons in the first layer by the number of neurons in the second layer. We also add the number of biases in the second layer.

$$P = \sum_{l=1}^{l-1} (N_l \times N_{l+1}) + N_{l+1}$$

Example

The input layer has 784 neurons and the output layer has 10 neurons.

If we have a hidden layer with 16 neurons, the number of weights is calculated as follows:

Layer 1: $784 \times 16 + 16 = 12560$

Layer 2: 16 imes 10 + 10 = 170

Total: 12560 + 170 = 12730

Inputs 392

MLP from raw data

We will test three different models with different number of neurons in the hidden layers.

For the first model, we chose a low number of neurons in the hidden layers to see how the model would perform with insufficient capacity. We hope to see the highest error rate in this model.

For the second model, we chose a number of neurons in the hidden layers that is higher than the number of neurons in the input layer. We hope to see a better performance than the first model.

For the third model, we chose a high number of neurons in the hidden layers to see how the model would perform with a high capacity. We hope to see the lowest error rate in this model, but we also expect to see overfitting.

We have the same number of inputs and outputs for all models. The input layer has 784 neurons and the output layer has 10 neurons.

Conclusion of the first exercise

First model has the highest error rate, as expected, because it has the lowest capacity.

The second model has a better performance than the first model, but it is still not as good as the third model.

The third model has the lowest error rate, but it is also the model with the highest capacity. We can see in the performance plots that the third model is overfitting the training data.

MLP form HOG

We will test three different models with different number of pix_p_cells, orientations and hidden neurons.

The first one, we will keep the parameters as we got them in den notebook.

For the second one, we will increase the number of pix_p_cells to 7 and increase the hidden neurons to 16.

For the third one, we will increase the number of orientations to 16.

Conclusion of the second exercise

The first model has the lowest performance, as expected, because it has the lowest capacity. But it has still a good performance: ~80% accuracy. This is better than the first model of the first exercise which has the same capacity.

The second model has a better performance, but the training stops at ~40 epochs. This is probably because the model is overfitting the training data.

The third model has the best performance, but it is also the one which overfits the most. It begins to overfit the training data at ~20 epochs.

CNN

In this exercise, we will test three different models with different number of neurons in the feedforward part. We will start with a low number of neurons and increase the number of neurons in each model.

Conclusion of the third exercise

The first model has the lowest performance, as expected, because it has the lowest capacity. It has the worst performance from all first models with a ~36% accuracy.

The second model has a better performance, but the training isn't quite finished with 50 epochs. This shows in the confusion matrix, where it only gets to ~93% accuracy.

The third model has the best performance, but it is also the one which overfits the most. It begins to overfit the training data at \sim 20 epochs. It still does have the best performance of this experiment with a \sim 97% accuracy.

CNN for chest x-ray pneumonia recognition
